Predictor variable

Peak ground acceleration

Nonparametric regression

### ABSTRACT

Earthquake research has not yielded promising results, because earthquakes have uncertain data parameters and one of the methods to overcome the problem of uncertain parameters is the non-parametric method, namely Multivariate Adaptive Regression Splines (MARS). Sumbawa Island is part of the territory of Indonesia and is in the position of three active earth plates so that Sumbawa is prone to earthquake hazards, therefore this research is important to do. The purpose of this study is to analyze the prediction of earthquake hazard on the island of Sumbawa by using the non-parametric MARS and Peak Ground Acceleration (PGA) methods to determine the risk of earthquake hazard. The method used in this study is MARS which has two stages in completing, namely Forward Stepwise and Backward Stepwise. The results of this study based on testing and parameter analysis obtained a Mathematical model with 11 basis functions (BF) that contribute to the response variable, namely (BF) 1,2,3,4,5,7,9,11, and the basis functions do not contribute 6, 8, and 10. The predictor variables that have the greatest influence are 100% Epicenter Distance and 73.8% Magnitude. The conclusion of this study is based on the highest PGA values in the areas most prone to earthquake hazards in Sumbawa, namely Mapin Kebak, Mapin Rea, Pulau Panjang and Pulau Saring.

## 1 INTRODUCTION

Earthquakes are natural disasters that can cause minor to severe damage. Many lives and property were lost as a result of the earthquake. Research on earthquakes to date has not provided significant results to be able to determine the causative factors, or when the earthquake occurred. Many studies have been carried out but the problem is that the data related to earthquakes is uncertain, and involves big data as a result of recording the accelerograph machine so that an appropriate method [22] needed to perform predictive analysis based on past data. Research that has been carried out using various methods, such as classification and regression methods, Artificial Neural Networks (ANN), Support Vector Regression (SVR), Hybrid Neural Network (HNN), or others, but these methods use a parametric approach, while earthquake data The earth is uncertain, so an appropriate method is needed, namely a non-parametric approach such as the Multivariate Adaptive Regression Spline (MARS) method. Earthquakes can occur anywhere, including on Sumbawa Island, West Nusa Tenggara. Sumbawa Island is part of the Indonesian archipelago and is in a position to the west of the Alas Strait. Sumbawa with an area of 15,448 square km and has an active volcano and once erupted violently in 1815 and had an impact on the whole world with changes in weather and the distribution of volcanic ash up to 1,300 km. The existence of Sumbawa is geologically in the position of the western and eastern island arcs due to the subduction of the Australian plate at the continental boundary of the Indo-Pacific plate which is to the south of Sumbawa Island. Because Sumbawa is at a plate meeting position, Sumbawa Island is an area that is prone to tectonic earthquakes. History shows Sumbawa often experiences earthquakes with a magnitude scale of more than 5 with a depth of less than 70 Kilometers. Many methods have been developed and [61] arch on earthquake prediction is included in the scope of data mining research [1]. Data mining is grouped into two, namely predictive data mining and descriptive data mining. Data mining in principle is the process of finding certain patterns and knowledge from large data sources [1]. In the data mining process, mathematical functions are needed, such as Association, Correlation, Classification, Regression, and Clustering functions [1]–[3]. Many methods are used [54] the data mining process and one of them is the Multivariate Adaptive Regression Spline (MARS) method [4]–[6]. MARS is a nonparametric method for solving high-dimensional data problems and is used to find the relationship between predictor variables and response variables. MARS is very effectively used in processing earthquake prediction data mining as will be done in this study.

Research related to earthquake prediction using various methods has been carried out, such as the use of the [32] Artificial Neural Network method [7]. The study was conducted to calculate sixty seismic features with seismological concepts such as the Gutenberg-Richter law [29] aftershock frequency, seismic energy release, seismic change rate, and total repeat time. Furthermore, to extract the relevant features, Maximum Releva [29] and Minimum Redundancy (MRMR) are used. In making earthquake predictions, classification methods are used with Vector Regressor (SVR) and Hybrid Neural Network (HNN). The numerical results obtained after being compared with previous prediction studies show an increase in prediction performance for all regions considered [7]. This study evaluates earthquake events for 50 years with a magnitude range of 0 to 8 Mw, and the use of Artificial Neural Networks is used to analyze earthquake data to produce [40] tions of the next earthquake magnitude [8]. Comparison Three methods, namely Levenberg Marquardt Backpropagation (LMBP) [64] current Neural Network (RNN), and Radial Basis Function (RBF) have also been carried out to predict and eval [52] four different statistical measures. The results of the three RNN methods provide better predictive accuracy [9], [10]. The Artificial Neural Network (ANN) is used to predict aftershocks for the next five days, after earthquakes occur in several areas in Indonesia. Six clusters were used for analysis using Valley Tracing and Hill Climbing algorithms, while Hierarchical K-means were applied to the group data set. From the evaluation results, it gives better results in predicting the occurrence of aftershocks of or greater than 6 magnitude [11]. Another technique that uses the Fuzzy Logic System method to model mathematically in predicting earthquakes, and the results of evaluating MAPE and MSE values for the best model for predicting earthquakes is to provide 7 inputs and 1 output from the fuzzy model [12]. The use of the Innovative Mathematical Model (IMM) for the analysis of earthquake events in the last 20 years, and the Poisson distribution and Spatial Connection methods for each earthquake zone and identify patterns of random earthquake events [13].

Earthquake data is random and contains a high element of uncertainty, so it is necessary to choose the right method in carrying out predictive analysis, so the MARS method is very suitable to be applied in predicting earthquake data [14]. Another study with MARS and C-MARS which explains that Ground Motion Prediction Equations (GMPEs) is an en [57] cal relationship that is used to determine the response of the ground peak at a certain distance from the earthquake source. Conic Multivariate Adaptive Regression Splines (CMARS) method on available data sets to obtain new GMPE. In the CMARS model, PGA and PGV values are used as dependent variables, while three other parameters such as moment magnitude (Mw), station location conditions (Vs30) and distance from earthquake source (Rjb) are used as independent variables. The findings of this study indicate that CMARS can be used effectively to predict PGA and PGV values at various distances from the earthquake source. The results were compared with the other three GMPEs and CMARS were more effective for ground motion prediction purposes [15]–[50].

The purpose of this study is to develop research using the MARS method in a case study of the earthquake that occurred on Sumbawa Island, Indonesia. This research is different from earthquake prediction research conducted by other researchers, because the basic nature of earthquake research is influenced by bedrock conditions where the location of the earthquake varies from one area to another which has different soil and rock structures. This research was conducted by developing the function of the Mathematical model formed by MARS according to the condition of the regional bedrock on Sumbawa Island. This researcher will use three predictor variables to find correlations in predictive analysis. This study will produce an analysis of predictions of earthquake-prone areas on Sumbawa Island based on Peak Ground Acceleration data with the highest value.

## 2 RESEARCH METHOD

### 2.1. Multivariate Adaptive Regression Spline (MARS)

The MARS method is a nonparametric regression method that is used to overcome the problem of high-dimensional data, which is used to determine the pattern of the relationship between the response variable and the predictor variable whose regression curve is not known [19]. In data mining management, predictions can be completed in two ways, namely Parametric Regression and Nonparametric Regression. These two approaches are commonly used as statistical methods and are widely used as methods for investigating and modeling relationships between variables [20]. The MARS method can overcome the shortcomings of Recursive Partitioning Regression (RPR) by producing a continuous model at knots and identifying the presence of an additive linear function. The MARS method can be solved by two stages of the algorithm, namely the Forward Stepwise model and the Backward Stepwise model [18], [21], [22]. The first stage, namely the Forward Stepwise Algorithm, is used for a combination of basis functions (BF), maximum interaction (MI), and minimum observation (MO). to find the relationship between the response variables and predictor variables. This research has determined that the response variable is Peak Ground Acceleration (PGA) and the predictor variables are depth, magnitude (Mw), epicenter distance (Repi). Furthermore, the second stage of the Backward Stepwise model is used as a simplification of the basis function (BF) obtained from the Forward Stepwise stage. The basis function (BF) which has no contribution or makes a small contribution to the response variable will be eliminated at the backward stepwise model stage. This deletion process will have the effect of decreasing the number of least squares of the remainder. In general, the Nonparametric Regression model can be presented as in equation (1) [23]–[25].

$$y_i = f(x_i) + \varepsilon_i \quad (1)$$

Where  $y_i$  is the response variable on observation  $i$ ,  $f(x_i)$  is vector predictor variable function, and  $\varepsilon_i$  is a free error  $i$ . The determination of the independent variable greatly determines the results of the model built using the MARS method so that the MARS model is flexible and its basic functions can be explained in equations (2) and (3). Equations (2) and (3) seem to have almost the same function, so they can be called reflected pairs. The goal is reflected pairs on each variable  $x_j$  on each observation  $x_{i,j}$  on the knots of the variable. So that a truncated linear function is formed from the basis function as in equation (4). The MARS model starts from equation (5).

$$(x - r)_+ = \begin{cases} x - r, & \text{if } x > r, \\ 0, & \text{otherwise} \end{cases} \quad (2)$$

and

$$(x - r)_+ = \begin{cases} r - x, & \text{if } x < r, \\ 0, & \text{otherwise} \end{cases} \quad (3)$$

$$r = \{(x_j - r)_+, (r - x_j)_+ | r \in \{x_{1j}, x_{2j}, \dots, x_{Nj}\}, j = 1, 2, \dots, p\} \quad (4)$$

$$f(x) = \beta_0 + \sum_{m=1}^M \beta_m \beta_m(x), \quad (5)$$

Where  $M$  is the number of basis functions that make up the function model.  $\beta_m(x)$  is a basic function formed by a single element or by multiplying two or more elements contained in  $r$ , multiplied by the coefficient  $\beta_m$ . The  $m$  basic function can be explained into the basis function as shown in equation (6). Where  $K_m$  is the number of truncated linear functions times the basis function to  $m$ . For  $X_{k_j}^m$  is the input variable associated with the truncated function in the  $m$ th basis function.  $\tau_{k_j}^m$  is the value of knot variable  $\tau_{k_j}^m$ . While  $S_{k_j}^m$  is operator +/- which is worth 1 or -1.

$$\beta_m(x^m) = \prod_{j=1}^{K_m} [S_{k_j}^m (X_{k_j}^m - \tau_{k_j}^m)]_+, \quad (6)$$

The MARS model is flexible and can be used to overcome the weaknesses of recursive partition regression by increasing the accuracy of the model. The MARS model is run with a two-stage algorithm, namely Forward Stepwise and Backward Stepwise. Then the algorithm will determine the value of knots in the continuous model and minimize the value of Generalized Cross Validation (GCV) to find the best model. GCV measurement can be seen in equation (7). Where  $y_i$  is Variabel response,  $x_i$  is Variabel predictor,  $N$  is the number of observations,  $\hat{f}_M(x_i)$  is the estimated value of the dependent variable on the  $M$  basis function on  $x_i$ ,  $M$  is maximum number of base functions,  $\hat{C}(M)$  is  $C(M) + d.M$ ,  $C(M)$  is  $\text{Trace}[B(B^T B)^{-1} B^T] + 1$ , where  $B$  is a matrix of  $M$  basis functions, and  $d$  is value when each base function reaches optimization ( $2 \leq d \leq 4$ ).

$$GCV(M) = \frac{\frac{1}{N} \sum_{i=1}^N [y_i - f_M(x_i)]^2}{\left[1 - \frac{C(M)}{N}\right]^2} \quad (7)$$

## 2.2. Peak Ground Acceleration (PGA)

Maximum Ground Acceleration (PGA) is the maximum ground vibration acceleration that occurs in an area caused by an earthquake. A large PGA value in an area usually has a large damage impact on the area at the center of the earthquake. The unit of PGA value is usually expressed in units of Gravitational Acceleration "gal". One way to get the PGA value is by using the empirical calculation of the Attenuation function. The attenuation function is used to determine the relationship between ground vibration intensity, magnitude and distance from an area to the epicenter of the earthquake. There are several factors that affect the attenuation function, namely the earthquake mechanism, the distance of the epicenter and the condition of the ground location. This research is to get the PGA value using the Attenuation function of the Joyner and Boore Attenuation equations as in the following formula (8) [26] [27].

$$PGA \text{ (gal)} = 10^{(0.71+0.23(M-6)-\text{Log}(r)-0.0027r)} \quad (8)$$

$$r = \sqrt{R_{epi}^2 + 8^2} \quad (9)$$

Where M is the magnitude, and r is the root of  $(R_{epi}^2 + 8^2)$ . By assigning a value to 'M' and the value of 'r' in equation (9), the PGA value will be obtained. Furthermore, the research was carried out with Prediction analysis with previous selection/separation and selection of appropriate variables, for Responsive variables and Predictor variables. This study uses the response variable 'PGA' and the predictor variables are depth, magnitude (Mw), epicenter distance (Repi).

## 2.3. Data Collection

This study uses earthquake catalog data taken from sources on the USGS website (<https://earthquake.usgs.gov/earthquakes/search/>). The data was accessed on May 31, 2022 at 10:47 AM, and has been filtered with a magnitude of more than 4 Mw this is done because a Magnitude of less than 4 Mw does not have a significant impact or may not be felt at all. The coordinate position taken is -8,59491 South Latitude and 117,26121 East Longitude. Earthquake catalog data was obtained in a period of 20 years with a total of 105 records in the range of Magnitude 4 to the highest of 5.5 Mw. The data is processed by a selection system with a magnitude of more than 4 Mw, a depth of less than 250 Km and an earthquake center distance of less than 300 Km. data that is not in the provisions or ring will be deleted or not used because it does not cause damage. The data is processed for use in predictive analysis. 3 data variables have been determined, namely Magnitude, Epicenter Distance, and depth of the center of the earthquake location.

The earthquake prediction analysis process used the Multivariate Adaptive Regression Spline (MARS) method using the equation function number 6 and to get the minimum value of Generalized Cross Validation (GCV) used equation number 7. The SPM 8 software was used to predict earthquakes by analyzing the factors the parameter factor of the relationship between the predictor variable and the response variable. MARS works with two algorithms, namely the Forward Stepwise algorithm and the Backward Stepwise algorithm. Forward Stepwise algorithm is used to determine the combination of maximum basis function with maximum interaction and minimum observation (MO).

Maximum basis function for cross multiplying between variables that have linkage and correlation. Maximum Interaction (MI) to describe the maximum line in the basis function (BF) that can be traversed or past the knot point, and the minimum observation to obtain a minimum smoothing parameter value or in other words the minimum observation between knots. Furthermore, the Backward Stepwise algorithm is used to simplify the complexity of the formed mathematical model functions. This algorithm uses a regularization technique to minimize generalization errors by using the Tikhonov Regularization technique, which gives a penalty if the function of the Mathematical model that is formed is too complex. Peak Ground Acceleration (PGA) is used to determine whether an area is categorized as prone or not to earthquake hazards. A high PGA value in an area will have a high impact due to the occurrence of an earthquake. The PGA value is obtained from recording using an Accelerograph machine or by empirical calculations, and this study uses empirical calculations using the Joyner and Boore Attenuation functions, as in the equations of functions number 8 and 9.

## 3 RESULTS AND ANALYSIS

### 3.1. Results

The results of the study began with preprocessing the data to find the value of the epicenter distance and Maximum Ground Acceleration (PGA), to find the PGA value, the Joyner and Boore attenuation functions were used. After knowing the PGA value, the calculation and prediction analysis can be continued using the MARS method. At this stage, to get the best MARS model, it is necessary to test the data and to determine the best model by selecting the minimum GCV value. Peak Ground Acceleration (PGA) is the maximum ground vibration acceleration that occurs in an area caused by an earthquake. A large PGA

value in an area usually has a large damage impact on the area at the center of the earthquake. The unit of PGA value is usually expressed in units of Gravitational Acceleration "gal". One way to get the PGA value is by using the empirical calculation of the Attenuation function. The attenuation function is used to determine the relationship between ground vibration intensity, magnitude and distance from an area to the epicenter of the earthquake. There are several factors that affect the attenuation function, namely the earthquake mechanism, the distance of the epicenter and the condition of the ground location. This research is to get the PGA value using the Attenuation function of the Joyner and Boore Attenuation equations as in the following formula (8) and (9) [26]. From the results of processing earthquake data that occurred in Sumbawa from 2000 to 2021, the PGA value was obtained as shown in Table 1.

Table 1. PGA Value for Earthquake in Sumbawa

Furthermore, the research was carried out with Prediction analysis with previous selection/separation and selection of appropriate variables, for Responsive variables and Predictor variables. This study uses the response variable 'PGA' and the predictor variables are depth, magnitude (Mw), epicenter distance (Repi). The results of the selection of the appropriate type of variables in the prediction analysis, data can be obtained as shown in Table 2. The results of the prediction analysis using the MARS method using the Forward Stepwise algorithm and the Backward Stepwise algorithm based on a combination of BF, MI and MO, the results are in the form of training data. The results of the MARS regression based on the training data are as shown in Table 3.

### 3.2 Testing and analysis

In predictive analysis, a statistical analysis test is needed to obtain the results of hypothesis testing and determine the level of significance. The significance level is meant to get the parameter significance. Hypothesis testing is required to use statistical analysis to determine the significance of parameters with the suitability of the mathematical model obtained. This research in testing the analysis of mathematical models using partial regression coefficient test. In testing the partial regression coefficient, the following formula is needed:

$$H_0 : \alpha_1 = \alpha_2 = \alpha_3 = \alpha_5 = \alpha_7 = \alpha_8 = \alpha_9 = \alpha_{11} = 0$$

$$H_1 : \text{there is at least one } \alpha_m \neq 0;$$

$$m=1,2,3,4,5,7,9,11 \text{ (significant model)}$$

- Significant level,  $\alpha = 0,05$
- Statistic test :  $t_{count} = \frac{\hat{\alpha}_m}{Se(\hat{\alpha}_m)}$  with  $Se(\hat{\alpha}_m) = \sqrt{var(\hat{\alpha}_m)}$
- Critical area : refuse  $H_0$  if  $t > t_{(\frac{\alpha}{2}, 61)}$  or P-value  $< \alpha$

P-value in statistical tests. used to determine the magnitude of the opportunity, to state the status Reject the null hypothesis or ( $H_0$ ) with the actual condition ( $H_0$ ) is true. As shown in Table 3 (results of training data) that the P-value is less than 0.05, or in other words, every  $m$   $\alpha$  or ( $m < 0.05$ ) so that the  $H_0$  status is rejected. This means that each coefficient  $\alpha_1, \alpha_2, \alpha_3, \alpha_4, \alpha_5, \alpha_7, \alpha_9, \alpha_{11}$  has a significant effect on the mathematical model obtained. Based on the significance level of 5%, the mathematical model in formula (10) is significant, so it can be used in predictive analysis of the PGA value for earthquake data sets in Sumbawa. Furthermore, after knowing the suitability of the parameters and mathematical models obtained based on testing, it is concluded that the variables that affect the PGA value are epicenter distance (R-epi), magnitude (Mw), and depth (Depth).

### 3.3. Discussion

It can be seen in table 3 that the parameters formed with 11 basis functions that contribute to the response variable are Basis functions 1,2,3,4,5,7,9, and 11. There are several basis functions that do not contribute to the response variable, namely base function 6, 8 and 10 then the basic function is omitted or deleted. The results of testing the data at the Backward Stepwise stage by simplifying the function can be obtained a Mathematical model as in formula 10.

$$Y = 0.042863 - 0.00130501 * BF1 + 0.00151234 * BF2 + 0.0221103 * BF3 - 0.0233377 * BF4 + 0.00106639 * BF5 + 0.000377886 * BF7 + 0.000305277 * BF9 + 0.000391561 * BF11; \quad (10)$$

$$\text{MODEL PGA} = \text{BF1 BF2 BF3 BF4 BF5 BF7 BF9 BF11};$$

Where  $Y_{(PGA)}$  is the result of PGA Prediction analysis with the MARS model with the contribution of each basis function (BF) as follows:

$$\begin{aligned} \text{BF1} &= \max(0, \text{REPI} - 50.3651); \\ \text{BF2} &= \max(0, 50.3651 - \text{REPI}); \\ \text{BF3} &= \max(0, \text{MW} - 5.1); \\ \text{BF4} &= \max(0, 5.1 - \text{MW}); \\ \text{BF5} &= \max(0, \text{MW} - 4.8) * \text{BF2}; \\ \text{BF7} &= \max(0, \text{REPI} - 41.4528) * \text{BF4}; \\ \text{BF9} &= \max(0, \text{REPI} - 64.7445); \\ \text{BF11} &= \max(0, \text{REPI} - 44.9069); \end{aligned}$$

Based on the best MARS model, the predictor variable inference that affects PGA is obtained according to the smallest GCV value sequentially based on the percentage of its contribution, namely the distance of the epicenter (Repi), the magnitude (Mw), and the depth (Depth). As shown in Table 4, which describes the interactivity of the predictor variable's contribution to the response variable.

Table 4. Interactivity of Predictor Variable Contributions

Variable	Importance	-gcv
REPI	100.00000	0.00023
MW	73.80473	0.00012
DEPTH	0.00000	0.00000

It can be seen in Table 4 that the most influential variables in the PGA value are the Epicenter Distance (Repi) of 100% and the Magnitude (Mw) of 73.8%, while the depth (Depth) does not contribute at all or 0%. The test results to clarify the description of the interactivity of the variable contributions of each predictor variable can be seen in Figure 1 of the Three Dimensional graph of the contribution of the predictor variable to the response variable

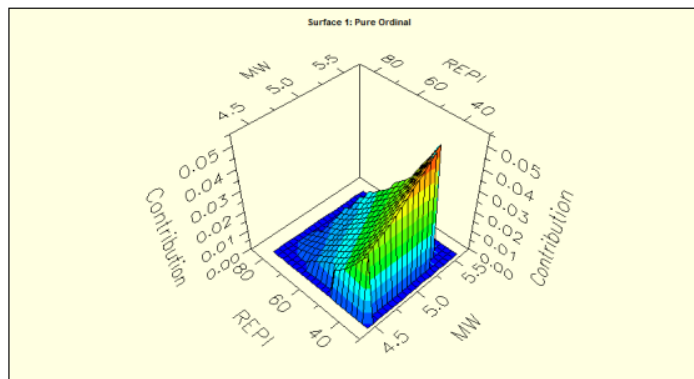

Figure 1. Graph of the Contribution of the Predictor Variable to the Response Variable

Seen in Figure 1, the three-dimensional graph shows that the lower the value of the epicenter distance (Repi) has the higher the contribution value to the Response variable and this means that the closer the epicenter distance has the higher the impact of damage caused by earthquakes. Likewise, it can be seen that the larger the value of the Magnitude (Mw) variable has a higher contribution value to the Response variable, meaning that the greater the magnitude value, the greater the damage caused by the earthquake. After going through the testing and validation of the Prediction Analysis results, the Regions in Sumbawa with the Highest Potential for Earthquake Hazards can be identified based on the highest PGA values referring to table 1, namely Mapin Kebak, Mapin Rea, Pulau Panjang and Pulau Saringgi. Based on the calculation of the PGA value which is influenced by the magnitude, depth, and distance of the earthquake location. In theory, based on a high PGA value, it will have a high impact on earthquake damage, although there are other factors that affect earthquake damage, such as the condition of the bedrock of the location. Based on the results of the prediction analysis by grouping the areas that have the highest earthquake vulnerability in Sumbawa, it can be used by policy makers to make rules in infrastructure development with special specifications in earthquake-prone areas.

Based on a literature search, no earthquake prediction research was found that specifically mapped areas on Sumbawa that are prone to earthquakes. However, other studies discuss in general, that Sumbawa Island is an earthquake-prone area as

explained by Haryadi, that the potential for an earthquake on Sumbawa Island is very likely to occur because in the northern part of Sumbawa Island there are micro tectonic plates that extend from Singaraja Bali to Dompu Regency, and there is a hemisphere fracture. This threat originates from the South which is at the bottom of the Indian Ocean because there is the Indo-Australian oceanic plate [28]. This is reinforced by the results of research conducted by Sabtaji who stated that the results of his research in West Nusa Tenggara Province, including the island of Sumbawa have a number of monthly earthquakes the most, namely the seismicity that occurred in August 2018 as many as 1,658 earthquake events [29]. Another research by Hidhajah stated that major earthquakes occurred [48] July to August 2018 which had an impact on food poisoning among refugees in the Alas area, Sumbawa district [30]. Based on the results of previous research, it can be concluded that the research that the authors conducted gave the same results that Sumbawa Island is included in areas that are prone to earthquake hazards, and the authors have been able to cluster Sumbawa Island which areas have the greatest risk of earthquake hazards.

#### 4 CONCLUSION

Based on earthquake catalog data from 2000 to 2021, this study produces an analysis of earthquake hazard predictions in Sumbawa using the MARS method which involves 11 basic functions. There is a close relationship between the predictor variable and the response variable with a percentage of 100 % epicenter distance and 73.8% magnitude. Based on PGA data, the Potential Areas with a great earthquake hazard in Sumbawa are Mapin Kebak, Mapin Rea, Pulau Panjang and Pulau Saringi. The results of the analysis of earthquake hazard predictions in Sumbawa can be used as consideration in infrastructure development in Sumbawa, so as to minimize the risk of earthquake hazards. Furthermore, this research can be developed by adding the number of predictor variables and the number of basis functions so as to provide more accurate prediction results.

#### 5 ACKNOWLEDGEMENTS

Praise be to God Almighty who has given His Grace so that this paper can be completed for processing in publication. Thank you very much to the Chancellor of Bumigora University, the head of LPPM, and all parties who directly or indirectly assisted in the process of preparing and publishing this paper.

#### 6 DECLARATIONS

##### AUTHOR CONTRIBUTION

In this study compiled by the authors who are divided into their respective tasks. Dadang Priyanto Compile, analyze the methods used, system testing and provision of software in research. Bambang Krismono Designing interfaces and creating data structures, making tables and graphs. Deny Jollyta, conducted a theoretical study and comparison of methods, as well as analysis of the results of PGA and Hairani collecting data and the initial process of processing the data in calculating the PGA value with the Attenuation function.

##### FUNDING STATEMENT

In this research did not receive grants from anywhere including the public, commercial, or non-profit sectors.

##### COMPETING INTEREST

In this study, there are no reserves related to competing financial, public and institutional interests.
